THE NORMAL FORM AND THE HOST, PROVED

THE NORMAL FORM · THE RECORD, THE TRANSFER, THE VALUE

THE RECORD
The registration keeps every even number and forgets which split realizes it; on the record the value holds with no premise.

`recFrame_value · record_has_the_value`

THE TRANSFER · THE ONE BIT
The value of a frame is exactly the transfer of the value from its record to the frame: the antecedent a theorem, the implication the whole content.

`normal_form · value_from_the_cargo_loop`

THE VALUE
On the arithmetic frame the value is the Goldbach statement in its standard form, by theorem: the sentence is the bit.

`binding · the_sentence_is_the_bit`

WHAT THE NORMAL FORM PROVES ON THE ROW, WITH NO PREMISE

The bit is the act
The transfer holds exactly when the act stands.

`bit_is_the_act`

Self-recursion
The record is self-recursive with no premise; the frame exactly when it carries the value.

`record_is_self_recursive`
`self_recursion_at_frame`

The bit is keyed
The transfer holds on the calm frame and fails on the counter frame.

`bit_is_keyed`
`record_self_recursion_does_not_transfer`

The record decides nothing
Two coherent frames share a record and split on the value; no principle true of every record decides it.

`record_decides_nothing`
`no_record_principle_decides`

Every route passes the bit
Any premise that yields the value yields the transfer, in any vocabulary.

`every_route_passes_the_bit`
`keyless_forces_nothing`

No uniform answer
Across the frames of the row the transfer is neither always true nor always false.

`no_uniform_answer · denial_is_the_bits_denial`

THE HOST AND THE BINDING, PROVED · PART B OF THE MASTER AND THE MATHLIB BINDING

The binding is a theorem
The value of the arithmetic frame is the Goldbach statement in its standard form; no reader's identification stands between.

`binding · goldbach_iff_std`

Every even number has its seat
n = 2k with the mirror fixing k: the one point where a split and its mirror coincide.

`every_even_has_its_seat · mirror_has_one_seat`

The finite form
A passing check at k proves every even number to 2k a sum of two primes; the statement is exactly a certificate at every height.

`real_part_of_check`
`goldbach_iff_check_at_every_height`

Bound to Mathlib's primes
The kernel's primality is Mathlib's Nat.Prime, and the kernel's statement is Mathlib's Goldbach conjecture.

`kprime_iff_prime · goldbach_std_iff_mathlib`

The three forms are one
The binary statement is Euler's form, and it gives the ternary form.

`binary_iff_euler · binary_gives_ternary`
`the_three_forms_are_one`

The kernel's own computation
Every even number from 4 to 2000 a sum of two primes, by the kernel's own check, read in the standard form.

`executed_region_std · executed_check_at_1000`
